Abstract

The India-based Neutrino Observatory (INO) will host a 50 kt magnetized iron calorimeter (ICAL@INO) for the study of atmospheric neutrinos. Using the detector resolutions and efficiencies obtained by the INO collaboration from a full-detector GEANT4-based simulation, we determine the reach of this experiment for the measurement of the atmospheric neutrino mixing parameters ($\sin^2 \theta_{23}$ and $|\Delta m_{32}^2|$). We also explore the sensitivity of this experiment to the deviation of θ_{23} from maximal mixing, and its octant.

1 Introduction

Neutrino flavor oscillations have been established beyond any doubt by a series of outstanding results from atmospheric [1], solar [2], reactor [3–6] and accelerator [7–9] neutrino experiments. Neutrino flavor oscillations require neutrinos to be massive and mixed, and they have thus provided the first unambiguous hint for physics beyond the standard model of elementary particles. The neutrino mixing matrix, called U_{PMNS} [10,11], can be parameterized in terms of three mixing angles θ_{12} , θ_{13} , θ_{23} , and a charge-parity violating (CP) phase δ_{CP} . In addition, if neutrinos were Majorana particles, we would have two Majorana CP phases α_1 and α_2 as well. The frequencies of neutrino oscillations are governed by two mass squared differences, Δm_{21}^2 and Δm_{31}^2 , where we define $\Delta m_{ij}^2 = m_i^2 - m_j^2$. The so-called solar neutrino oscillation parameters θ_{12} and Δm_{21}^2 have been measured from the combined analysis of the KamLAND reactor $\bar{\nu}_e$ data and the solar neutrino data. The so-called atmospheric neutrino oscillation parameters θ_{23} and $|\Delta m_{31}^2|$ are mostly constrained by the Super-Kamiokande (SK) atmospheric and MINOS ν_μ

disappearance data. The third and the last mixing angle θ_{13} is the latest to be measured by a series of accelerator and reactor experiments. After decades of speculation on whether θ_{13} was zero, data from these experiments have revealed that the value of θ_{13} is not only non-zero, it is in fact just below the previous upper bound [12] from the Chooz experiment. Accelerator-based neutrino experiments T2K and MINOS have both observed ν_e appearance events from a beam of ν_μ that indicates a non-zero value of θ_{13} . The short baseline reactor neutrino experiments Daya Bay, RENO and Double Chooz have excluded $\theta_{13} = 0$ at 5.2σ , 4.9σ and 3.1σ respectively from $\bar{\nu}_e$ disappearance. Their best fit values are $\sin^2 2\theta_{13} = 0.092 \pm 0.016(\text{stat}) \pm 0.005(\text{syst})$ [4], $\sin^2 2\theta_{13} = 0.113 \pm 0.013(\text{stat}) \pm 0.019(\text{syst})$ [5] and $\sin^2 2\theta_{13} = 0.109 \pm 0.030(\text{stat}) \pm 0.025(\text{syst})$ [6], respectively. We summarize our current understanding of the neutrino oscillation parameters in Table 1.

Parameter	Best Fit Value	3σ Ranges
$\sin^2 \theta_{12}$	0.307	0.259-0.359
$\sin^2 \theta_{23}$	0.386 0.392	0.331-0.637 (NH) 0.335-0.663 (IH)
$\sin^2 \theta_{13}$	0.0241 0.0244	0.0169-0.0313 (NH) 0.0171-0.0315 (IH)
Δm_{21}^2 (eV ²)	7.54×10^{-5}	$6.99\text{--}8.18 \times 10^{-5}$
$ \Delta m_{31}^2 $ (eV ²)	2.43×10^{-3} 2.42×10^{-3}	$2.19\text{--}2.62 \times 10^{-3}$ (NH) $2.17\text{--}2.61 \times 10^{-3}$ (IH)

Table 1: A summary of the current values of the neutrino oscillation parameters. The values are taken from [13]. NH and IH indicate the limits applicable if the mass hierarchy is normal and inverted, respectively.

While the above experiments continue to improve the precision on the mixing angle θ_{13} , the focus has now shifted to the determination of the other unknown parameters in the neutrino sector. These include the CP violating phase δ_{CP} and the sign of Δm_{31}^2 . Though the current global analyses [13, 14] have started to provide some hints about the value of δ_{CP} , these are still early days, and better data from dedicated experiments would probably be required before one could make any definitive statement on whether CP is violated in the lepton sector as well. The answer to this question would have far-reaching implications, as a positive answer would lend support to the idea of baryogenesis via leptogenesis during the early universe.

Determining the sign of Δm_{31}^2 is also of crucial importance, since its knowledge is essential for constructing the mass spectrum of neutrinos. This sign can be extracted via the detection of earth matter effects in atmospheric and accelerator-based neutrino beams. Proposed detectors aiming to observe earth matter effects in atmospheric neutrinos include the Iron CALorimeter (ICAL) at the India-based Neutrino Observatory (INO) [15], megaton water Cerenkov detectors such as the Hyper-Kamiokande (HK) [16], large liquid argon detectors [17, 18] and a gigaton-class ice detector such as the Precision IceCube Next Generation Upgrade (PINGU) [19, 20]. The accelerator beam neutrino experiment NO ν A [21], which will start operating soon, will also be sensitive to the mass hierarchy.

The other neutrino parameter that is yet to be measured is the absolute neutrino mass scale, on which currently we have only upper bounds from cosmological data [22–24], from neutrinoless

double beta decay [25,26], and from tritium beta decay experiments [27,28]. Finally, the neutrinoless double beta decay experiments will also answer the most fundamental question – whether neutrinos are Dirac or Majorana particles. If neutrinos are indeed Majorana, the neutrinoless double beta decay experiments might also have a chance to shed light on the Majorana phases in the far future.

INO is an experiment [15] proposed to study atmospheric neutrinos, employing the ICAL that can distinguish between μ^+ and μ^- , and will have good energy as well as direction resolution for muons. The magnetic field will enable it to distinguish between neutrinos and anti-neutrinos, hence allowing identification of the neutrino mass hierarchy. It will be located in the Bodi West Hills in the Theni district of Tamil Nadu in Southern India. The ICAL cavern will be located under a 1589 m high mountain peak. This peak provides a minimum rock cover of about 1 km in all directions to reduce the cosmic muon background. The detector is designed to consist of 150 alternate layers of 5.6 cm thick iron plates and glass Resistive Plate Chambers (RPCs) stacked on top of each other. The total mass of the detector will be about 50 kt. The iron plates act as the target mass for neutrino interactions and the RPCs are the active detector elements that give the trajectory of the muons and hadrons passing through them. Iron will be magnetized to a field of about 1.3-1.5 Tesla.

The main physics objective of ICAL is the determination of the neutrino mass hierarchy through the observation of earth matter effects in atmospheric neutrinos. In a recent analysis [29] performed by members of the INO collaboration, it was shown that data from this experiment along with that from the reactor and long baseline experiments T2K and NO ν A could determine the neutrino mass hierarchy at the $2.2\sigma - 5.5\sigma$ C.L., depending on the true values of the parameters θ_{13} , θ_{23} and δ_{CP} , with $50 \text{ kt} \times 10 \text{ years}$ of exposure.

In this paper, we explore in detail the potential for measuring the neutrino parameters θ_{23} and $|\Delta m_{32}^2|$ in the ICAL@INO experiment using atmospheric neutrinos. The precision on both these parameters is expected to improve from data coming from the currently operating and soon-to-start experiments using accelerator-based neutrino beams (MINOS, T2K and NO ν A) as well as atmospheric neutrinos (at Super-Kamiokande and IceCube Deep Core). Here we compare the potential of the ICAL@INO atmospheric neutrino experiment vis-a-vis the expected sensitivity of these complementary experiments. For our simulation of atmospheric neutrino events in ICAL@INO we use the software tailored and developed by the INO collaboration and present results obtained using the detector resolutions and efficiencies obtained from detailed simulations of the ICAL detector [30,31]. We restrict ourselves to using the information about the energy and direction of the muons produced in the detector. The results reported here are a part of the simulation and physics analysis being performed by the INO collaboration towards the full understanding of the capabilities of this experiment and a realistic study of its sensitivity reach. (Studies that explore the reach of a magnetized iron calorimeter for neutrino mixing have been performed in the past [32,33], however this is the first time that we use the realistic ICAL detector simulations in the analysis.)

The paper is organized as follows. In section 2 we describe the detector simulation procedure for the ICAL detector, and the detector response for muons obtained from the GEANT4 simulations which are used in this work. In section 3, we outline our analysis procedure. In section 4, we discuss the results of our analysis, presenting the reach of the ICAL@INO for θ_{23} and $|\Delta m_{32}^2|$. Section 5 summarizes our findings.

2 Simulation Framework and the Detector Response for Muons

Neutrinos interact in the ICAL detector with nucleons and electrons, giving rise to leptons and hadrons. As the outgoing lepton and hadrons propagate through the detector volume, they cross one or more RPC layers to give hit points in the RPCs. For every hit point, the (x, y) position, time of hit and the RPC layer number are recorded. The information contained in the hit points is used to reconstruct the energy and direction of the particles. A muon passing through the ICAL detector gives hit points in several layers, which can be cleanly joined to form a track. In contrast, a pion or other hadron passing through the detector typically gives rise to a hadron shower with multiple hit points in a single layer which cannot be joined to form a track. The ICAL detector is optimized primarily to measure the muon momentum with a good precision. The muon charge identification efficiency is also high. The hadron energy and direction can be calibrated based on the number of hit points, and by combining the muon and hadron information, the neutrino momentum can be reconstructed, albeit with a coarser precision.

The detector simulation procedure is as follows. A GEANT4 [34,35] -based detector simulation package for ICAL has been developed. The secondary particles are first propagated inside the detector using the GEANT4 code, taking into account the energy losses, multiple scattering, and magnetic field. This gives the hit positions of the particles in the active detectors, i.e. RPCs. Next, this output is digitized and used as an input for the reconstruction of the particle energy and direction.

The reconstruction of the momentum of a particle is done in two steps. First, the topology of the digitized hit points is analyzed to find a possible muon track, and/or to find a hadron shower. Next, if the hit points are found to form a muon track, a Kalman Filter-based algorithm is used to reconstruct the initial energy, direction, and the vertex position of the muon. In case the hit points are identified as a hadron shower, the energy of the hadron is estimated by calibrating it against the number of hit points.

The muon response of the ICAL detector is parametrized in terms of the energy resolution (σ_E), direction resolution ($\sigma_{\cos\theta}$), reconstruction efficiency (ϵ_R) and the charge identification efficiency (ϵ_C). All these quantities are estimated as functions of the true muon energy (E_μ) and direction ($\cos\theta_\mu$), for μ^- and μ^+ . Here θ_μ is the zenith angle for the muon. Figure 1 shows the muon energy and direction resolutions, as well as the reconstruction and charge identification (CID) efficiencies for μ^- , for some specific muon zenith angles. The numbers for μ^+ are virtually identical. We note here that the reconstructed energy distribution of the muon is fitted with the Normal distribution function for $E_\mu \geq 1$ GeV, whereas for $E_\mu < 1$ GeV it is fitted to the Landau distribution function. In the present work, we have carried out the oscillation analysis with muon energy and direction ($E_\mu, \cos\theta_\mu$) as observables using simulated data.

The analysis in this paper is based only on the energy, direction, and charge of the muon, for the charged-current (CC) ν_μ events. The inclusion of information on hadron energy and direction is beyond the scope of this paper. The detector response to muons used in this work comes from the first set of simulations done with the ICAL code. These simulations are ongoing and are being fine-tuned. Hence the values of the resolution functions and efficiencies are likely to evolve along with the simulations.

Figure 1: The energy resolution (a), $\cos \theta_\mu$ resolution (b), the reconstruction efficiency (c), and the charge identification efficiencies (d), for μ^- as a function of the true muon energy and for three cases of true muon zenith angle. The red, green and blue lines are for the zenith angle bins with $\cos \theta_\mu = -0.35 \pm 0.05$, -0.55 ± 0.05 , -0.85 ± 0.05 , respectively.

3 Oscillation Analysis Procedure

The physics analysis of atmospheric neutrino events requires simulations which can be broadly classified into four steps : (i) neutrino event generation, (ii) inclusion of the oscillation effects, (iii) folding in the detector response, and (iv) the χ^2 analysis. These steps are described in detail in the following subsections.

3.1 Event Generation

We use the neutrino event generator NUANCE (version 3.5) [36] to generate the neutrino interactions. The atmospheric neutrino fluxes provided by Honda et al. [37] at the Super Kamiokande location are used.* The ICAL detector composition and geometry are specified as an input. NUANCE incorporates the differential cross section for charged-current (CC) and neutral-current

*The neutrino fluxes at Theni have not yet been incorporated in the NUANCE event generator.

(NC) interactions for all nuclear constituents of the materials used in the detector, for all neutrino flavors, and for all possible interaction processes. The quasi-elastic (QE), resonance (RS), deep inelastic (DIS), coherent (CO) and diffractive (DF) scattering processes are all included. The neutrino fluxes are then multiplied with the interaction cross-sections to calculate the event rates for all scattering processes and possible target nuclei. Event kinematics are generated based on the differential cross-sections.

The NUANCE output consists of the 4-momentum (p^μ) of the initial, intermediate and the final state particles for each event. To reduce the Monte Carlo (MC) fluctuations in the number of events given by NUANCE, we generate a very large number of neutrino interactions (an exposure of $50 \text{ kt} \times 1000 \text{ years}$) and scale it down to the desired exposure for the χ^2 analysis.

3.2 Inclusion of Oscillations

The total number of ν_μ events coming from the $\nu_\mu \rightarrow \nu_\mu$ and the $\nu_e \rightarrow \nu_\mu$ channels is given as

$$\frac{d^2 N}{dE_\nu d(\cos \theta_\nu)} = N_T \times N_D \times \sigma_{\nu_\mu} \times \left[P_{\mu\mu} \frac{d^2 \Phi_{\nu_\mu}}{dE_\nu d(\cos \theta_\nu)} + P_{e\mu} \frac{d^2 \Phi_{\nu_e}}{dE_\nu d(\cos \theta_\nu)} \right], \quad (1)$$

where N_T is the exposure time and N_D is the number of targets in the detector. Here Φ_{ν_μ} and Φ_{ν_e} are the fluxes of ν_μ and ν_e respectively, and $P_{\alpha\beta}$ is the $\nu_\alpha \rightarrow \nu_\beta$ oscillation probability. Since an exposure of 1000 years has to be taken to reduce the MC fluctuations, generating events using NUANCE for each set of oscillation parameters is extremely time consuming and practically impossible within a reasonable time frame. Therefore, we generate events for 1000 years of exposure using NUANCE only once and employ the event re-weighting method described below to take care of neutrino oscillations on this event sample for any given set of oscillation parameters.

To get the number of μ^- events from ν_μ that have survived oscillations, we generate the ν_μ interactions from NUANCE using the un-oscillated ν_μ flux in the neutrino energy range $0.5 - 100 \text{ GeV}$ and all neutrino zenith angles θ_ν . For a given $\cos \theta_\nu$, the path travelled between the production point and the detector is

$$L = \sqrt{(R + L_0)^2 - (R \sin \theta_\nu)^2} - R \cos \theta_\nu, \quad (2)$$

where R is the radius of the earth (6378 Km) and L_0 is the average height of the atmospheric neutrino production, taken here to be 15 km. The survival probability $P_{\mu\mu}$ for the neutrino energy E_ν and zenith angle θ_ν for a given event is calculated using the oscillation probability code included in NUANCE [36]. The details of this oscillation probability calculation are as described in [?]. We next impose the event re-weighting algorithm as follows. To decide whether an un-oscillated ν_μ event survives the oscillations to be detected as ν_μ , a uniform random number r is generated between 0 and 1. If $P_{\mu e} \leq r < P_{\mu e} + P_{\mu\mu}$, we keep this event as a ν_μ event. Otherwise this ν_μ is considered to have oscillated into a different flavor.

Similarly, to get the μ^- events from atmospheric ν_e converted to ν_μ due to flavor oscillations, we generate the ν_μ interactions from NUANCE using the un-oscillated ν_e flux in the neutrino energy range $0.5 - 100 \text{ GeV}$ and all neutrino zenith angles θ_ν . This then has to be folded in with the conversion probability $P_{e\mu}$. For that we again use the event re-weighting algorithm where for each event a random number r is generated between 0 and 1. If $r < P_{e\mu}$ we label the event as a ν_μ event, otherwise we discard it.

The ν_μ events from $\nu_\mu \rightarrow \nu_\mu$ as well as $\nu_e \rightarrow \nu_\mu$ oscillation channels are added to form the μ^- event sample. Similarly, we form the μ^+ event sample as well. Next, we read the muon momentum of all the events that we have collected after oscillations and bin them according to energy (E_μ) and direction ($\cos \theta_\mu$) of the muons. We bin the data in the energy range $E_\mu = 0.5$ - 15.5 GeV (300 bins) and $\cos \theta_\mu$ in the range -1 to $+1$ (20 bins) because our analysis threshold is 0.8 GeV and the muon reconstruction efficiency is very low below 0.5 GeV. We keep track of the numbers of μ^- and μ^+ events separately. At this stage, we have the distribution of muon events in terms of their “true” energy (E_μ) and the cosine of the zenith angle ($\cos \theta_\mu$).

Figure 2 shows the zenith angle distribution of μ^- events in the energy bin $2 - 3$ GeV before and after invoking oscillations using the re-weighting algorithm described above. We use the oscillation parameters described in Table 2 and take the exposure to be $50 \text{ kt} \times 10 \text{ years}$.

Parameter	$\sin^2 2\theta_{12}$	$\sin^2 2\theta_{23}$	$\sin^2 2\theta_{13}$	$\Delta m_{21}^2 (\text{eV}^2)$	$ \Delta m_{32}^2 (\text{eV}^2)$	δ_{CP}	Hierarchy
True Value	0.86	1.0	0.113	7.6×10^{-5}	2.242×10^{-3}	0.0	Normal

Table 2: True values of the neutrino oscillation parameters used in this paper

Figure 2: Zenith angle distribution of μ^- events for the bin $2 \text{ GeV} \leq E_\mu < 3 \text{ GeV}$, without and with flavor oscillations. The detector efficiencies have not been included here. The error bars shown here are statistical.

3.3 Folding in the Detector Response

Next, we fold in the detector response [30] to obtain the measured distribution of muons. We apply the reconstruction efficiency (ϵ_{R-}) for μ^- by multiplying the number of events in a given true

Figure 3: Zenith angle distribution of oscillated μ^- events for the bin $2 \text{ GeV} \leq E_\mu < 3 \text{ GeV}$, after taking into account detector efficiencies. The error bars shown here are statistical.

energy (E_μ) and true zenith angle ($\cos \theta_\mu$) bin with the corresponding reconstruction efficiency:

$$N_{\mu-}(E_\mu, \cos \theta_\mu) = \epsilon_{R-}(E_\mu, \cos \theta_\mu) \times N_{\mu-}^{\text{true}}(E_\mu, \cos \theta_\mu), \quad (3)$$

where $N_{\mu-}^{\text{true}}$ is the number of μ^- events in a given ($E_\mu, \cos \theta_\mu$) bin. Exactly the same procedure is used for determining the μ^+ events. The CID efficiency (ϵ_{C-} for μ^- and ϵ_{C+} for μ^+ event sample) is next applied as follows:

$$N_{\mu-}^C = \epsilon_{C-} \times N_{\mu-} + (1 - \epsilon_{C+}) \times N_{\mu+}, \quad (4)$$

where $N_{\mu-}$ and $N_{\mu+}$ are the number of μ^- and μ^+ events, respectively, given by Eq. (3). Now $N_{\mu-}^C$ is the number of μ^- events after taking care of the CID efficiency. All the quantities appearing in Eq. (4) are functions of E_μ and $\cos \theta_\mu$.

Figure 3 shows the zenith angle distribution of events obtained before and after applying the reconstruction and CID efficiencies. Compared to Fig. 2, one can notice that the number of events fall sharply for the almost horizontal ($\cos \theta_\mu \approx 0$) bins. This can be understood by noting from Figure 1(c) that the reconstruction efficiency for muons falls as we go to more horizontal bins. The reason for this is the ICAL geometry where iron slabs and RPCs are stacked horizontally. Hence muons that are close to the horizontal direction cross fewer RPCs and mostly travel in the passive iron part of the detector. Identifying these tracks therefore becomes extremely difficult and the reconstruction efficiency of the detector falls. The CID efficiency also falls for the more horizontal bins and the result is that there are hardly any events for bins with $-0.2 \leq \cos \theta_\mu < 0.2$.

Finally, the muon resolutions σ_E and $\sigma_{\cos \theta}$ are applied as follows:

$$(N_{\mu-}^D)_{ij} = \sum_k \sum_l N_{\mu-}^C(E_\mu^k, \cos \theta_\mu^l) K_i^k(E_\mu^k) M_j^l(\cos \theta_\mu^l), \quad (5)$$

where $(N_{\mu^-}^D)_{ij}$ denotes the number of muon events in the i^{th} E -bin and the j^{th} $\cos\theta$ -bin after applying the energy and angle resolutions. Here E and $\cos\theta$ are the measured muon energy and zenith angle. The summation is over the true energy bin k and true zenith angle bin l , with E_{μ}^k and $\cos\theta_{\mu}^l$ being the central values of the k^{th} true muon energy and l^{th} true muon zenith angle bin. The quantities K_i^k and M_j^l are the integrals of the detector resolution functions over the bins of E and $\cos\theta$, the measured energy and direction of the muon, respectively. These are evaluated as:

$$K_i^k(E_{\mu}^k) = \int_{E_{L_i}}^{E_{H_i}} dE \frac{1}{\sqrt{2\pi}\sigma_{E_{\mu}^k}} \exp\left(-\frac{(E_{\mu}^k - E)^2}{2\sigma_{E_{\mu}^k}^2}\right), \quad (6)$$

and

$$M_j^l(\cos\theta_{\mu}^l) = \int_{\cos\theta_{L_j}}^{\cos\theta_{H_j}} d\cos\theta \frac{1}{\sqrt{2\pi}\sigma_{\cos\theta_{\mu}^l}} \exp\left(-\frac{(\cos\theta_{\mu}^l - \cos\theta)^2}{2\sigma_{\cos\theta_{\mu}^l}^2}\right), \quad (7)$$

where $\sigma_{E_{\mu}^k}$ and $\sigma_{\cos\theta_{\mu}^l}$ are the energy and zenith angle resolutions, respectively, in these bins. We perform the integrations between the lower and upper boundaries of the measured energy (E_{L_i} and E_{H_i}) and the measured zenith angle ($\cos\theta_{L_j}$ and $\cos\theta_{H_j}$). For the extreme $\cos\theta$ bins, the bins are taken to be $(-\infty, -0.9)$ and $[0.9, +\infty)$ while integrating, and the events are assigned to the bins $[-1, -0.9]$ and $[0.9, 1]$, respectively. This ensures that no event is lost to the unphysical region and the total number of events does not change after applying the angular resolution. For $E_{\mu}^k < 1$ GeV, the integrand in Eq. (6) is replaced with the Landau distribution function, as the reconstructed energy distribution obtained from ICAL simulations [30] is specified in terms of this function.

Figure 4: Zenith angle distribution of μ^- events for the bin $2 \text{ GeV} \leq E_{\mu} < 3 \text{ GeV}$ before and after including energy and zenith angle resolution function. Here E and θ are the measured energy and measured zenith angle, respectively. The error bars shown here are statistical.

Figure 4 shows the zenith angle distribution of μ^- events before and after folding in the resolution functions. The angular dependence seems to get only slightly diluted. This is attributed to the good angular resolution of the detector.

Table 3 shows the total number of muon events with measured energy range 0.8-10.8 GeV at various stages of the analysis for an exposure of $50 \text{ kt} \times 10 \text{ years}$. Note the sharp fall in statistics due to the reconstruction efficiencies. The reconstruction efficiencies are particularly poor for the near-horizontal bins where the reconstruction of the muon tracks is very hard. The small increase in the number of events after applying the energy resolution function is due to the spill-over of events from the low-energy part of the spectrum to measured energies greater than 0.8 GeV. The spillover to the energy bins with $E_\mu > 10.8 \text{ GeV}$ is comparatively small. The zenith angle resolution leaves the number of muon events nearly unchanged.

	μ^-	μ^+
Unoscillated	14311	5723
Oscillated	10531	4188
After Applying Reconstruction and CID Efficiencies	4941	2136
After Applying ($E, \cos \theta$) Resolutions	5270	2278

Table 3: Number of muon events produced in CC ν_μ interactions at various stages of the analysis for an exposure of $50 \text{ kt} \times 10 \text{ years}$ in the energy range 0.8-10.8 GeV.

3.4 The χ^2 Analysis

For the χ^2 analysis, we re-bin the data in ten energy bins between $E = 0.8 - 10.8 \text{ GeV}$ with bin width 1 GeV, and twenty $\cos \theta$ -bins between $\cos \theta = -1$ to $+1$, with bin width 0.1. The simulated data for ICAL@INO is then statistically treated by defining the following χ^2 :

$$\chi_{\text{ino}}^2(\mu^-) = \min_{\xi_k} \sum_{i=1}^{N_E} \sum_{j=1}^{N_{\cos \theta}} \left[2(N_{ij}^{\text{pred}} - N_{ij}^{\text{obs}}) - 2N_{ij}^{\text{obs}} \ln \left(\frac{N_{ij}^{\text{pred}}}{N_{ij}^{\text{obs}}} \right) \right] + \sum_{k=1}^5 \xi_k^2, \quad (8)$$

with

$$N_{ij}^{\text{pred}} = N_{ij}^0 \left(1 + \sum_{k=1}^5 \pi_{ij}^k \xi_k \right). \quad (9)$$

Here N_{ij}^{pred} and N_{ij}^{obs} are the expected and observed number, respectively, of μ^- events (N_{ij}^D) in a given $(E, \cos \theta)$ bin, while N_E ($=10$) is the number of energy bins and $N_{\cos \theta}$ ($=20$) is the number of zenith angle bins. N_{ij}^{obs} is calculated for a set of assumed “true value” of the oscillation parameters, listed in Table 2. N_{ij}^0 is the predicted number of events for a given set of oscillation parameters without the systematic errors included. The systematic uncertainties are included via the “pull” variables ξ_k , one each for every systematic uncertainty σ_k . Here π_{ij}^k is the change in the number of events in the $(ij)^{\text{th}}$ bin caused by varying the value of k^{th} pull variable ξ_k by σ_k . For determining π_{ij}^k , we have used a procedure similar to the one described in [39].

In this analysis we have considered the following five systematic uncertainties. We take 20% error on the flux normalization, 10% error on cross sections, and an overall 5% error on the total

number of events. In addition, we take a 5% uncertainty on the zenith angle dependence of the flux, and an energy dependent “tilt error” is included according to the following prescription. The event spectrum is calculated with the predicted atmospheric neutrino fluxes and then with the flux spectrum shifted according to

$$\Phi_\delta(E) = \Phi_0(E) \left(\frac{E}{E_0} \right)^\delta \simeq \Phi_0(E) \left(1 + \delta \ln \frac{E}{E_0} \right), \quad (10)$$

where $E_0 = 2$ GeV and δ is the 1σ systematic tilt error, taken to be 5%. The difference between $\Phi_\delta(E)$ and $\Phi_0(E)$ is then included as the error on the flux.

For each set of oscillation parameters, we calculate the χ^2 separately for the μ^- and μ^+ data samples, and add them to obtain the total χ^2 as

$$\chi_{\text{ino}}^2 = \chi_{\text{ino}}^2(\mu^-) + \chi_{\text{ino}}^2(\mu^+). \quad (11)$$

Since in this analysis we are mainly interested in constraining θ_{23} and $|\Delta m_{32}^2|$, and the variation of θ_{12} or $|\Delta m_{21}^2|$ within the current error bars is observed not to affect the results, we take the value of these two parameters to be fixed to those given in Table 2. On the parameter $\sin^2 2\theta_{13}$, we impose a prior to allow for the uncertainty in its current measurement :

$$\chi^2 = \chi_{\text{ino}}^2 + \left(\frac{\sin^2 2\theta_{13}(\text{true}) - \sin^2 2\theta_{13}}{\sigma_{\sin^2 2\theta_{13}}} \right)^2, \quad (12)$$

where $\sigma_{\sin^2 2\theta_{13}}$ is the current 1σ error on $\sin^2 2\theta_{13}$, and is taken as 0.013 in our analysis. Of course, during the operation of INO, the error $\sigma_{\sin^2 2\theta_{13}}$ will decrease, and within a few years, $\sin^2 2\theta_{13}$ may be considered to be a fixed parameter.

4 Precision Measurement of $\sin^2 \theta_{23}$ and $|\Delta m_{32}^2|$

We start by presenting the reach of the ICAL for the parameters $\sin^2 \theta_{23}$ and $|\Delta m_{32}^2|$ separately. The true values of all parameters are given in Table 2. Note that we use the parameter Δm_{32}^2 ($= \Delta m_{31}^2 - \Delta m_{21}^2$) instead of $|\Delta m_{31}^2|$, the current limits on which are given in [13]. The χ^2 values as functions of $\sin^2 \theta_{23}$ and $|\Delta m_{32}^2|$ are shown in figs. 5(a) and 5(b), respectively. Note that the minimum value of χ^2 vanishes, since MC fluctuations in the observed data have been reduced due to the scaling from an exposure of $50 \text{ kt} \times 1000 \text{ years}$.

The precision on these parameters may be quantified by

$$\text{precision} = \frac{p_{\text{max}} - p_{\text{min}}}{p_{\text{max}} + p_{\text{min}}}, \quad (13)$$

where p_{max} and p_{min} are the largest and smallest value of the concerned oscillation parameters determined at the given C.L. from the atmospheric neutrino measurements at ICAL for a given exposure. We find that after 5 years of running of this experiment, ICAL would be able to measure $\sin^2 \theta_{23}$ to a precision of 20% and $|\Delta m_{32}^2|$ to 7.4% at 1σ . With 10 years exposure, these numbers improve to 17% and 5.1% for $\sin^2 \theta_{23}$ and $|\Delta m_{32}^2|$, respectively. The precision on $\sin^2 \theta_{23}$ is mainly governed by the muon reconstruction efficiency and is expected to improve with it. It will also improve as the systematic errors are reduced. If the flux normalization

Figure 5: The panel (a) shows the χ^2 as a function of $\sin^2\theta_{23}$ for $|\Delta m_{32}^2| = 2.242 \times 10^{-3} \text{ eV}^2$ and $\sin^2\theta_{23}(\text{true}) = 0.5$. The panel (b) shows the χ^2 as a function of $|\Delta m_{32}^2|$ for $\sin^2\theta_{23} = 0.5$ and $|\Delta m_{32}^2|(\text{true}) = 2.242 \times 10^{-3} \text{ eV}^2$.

error were to come down from 20% to 10%, the precision on $\sin^2\theta_{23}$ would improve to 14% for 10 years of exposure. Reducing the zenith angle error from 5% to 1% would also improve this precision to $\sim 14\%$. On the other hand, the precision on $|\Delta m_{32}^2|$ is governed by the ability of the detector to determine the value of L/E for individual events accurately. This depends on the energy- and $\cos\theta$ - resolution of the detector.

A few more detailed observations may be made from the χ^2 plots in fig. 5. From fig. 5(a) one can notice that the precision on θ_{23} when it is in the first octant ($\sin^2\theta_{23} < 0.5$) is slightly better than when it is in the second octant ($\sin^2\theta_{23} > 0.5$), even though the muon neutrino survival probability depends on $\sin^2 2\theta_{23}$ at the leading order. This asymmetry about $\sin^2\theta_{23} = 0.5$ stems mainly from the full three-flavor analysis that we have performed in this study. In particular, we have checked that the non-zero value of Δm_{21}^2 is responsible for the asymmetry observed in this figure. On the other hand, χ^2 asymmetry about the true value of $|\Delta m_{32}^2|$ observed in Fig. 5(b) is an effect that is present even with a two-flavor analysis.

The precisions obtainable at the ICAL for $\sin^2\theta_{23}$ and $|\Delta m_{32}^2|$ are expected to be correlated. We therefore present the correlated reach of ICAL for these parameters in figs. 6(a) and 6(b). These are the main results of our analysis. As noted above, our three-neutrino analysis should be sensitive to the octant of θ_{23} . Therefore we choose to present our results in terms of $\sin^2\theta_{23}$ instead of $\sin^2 2\theta_{23}$. Though the constant- χ^2 contours still look rather symmetric about $\sin^2\theta_{23} = 0.5$, that is mainly due to the true value of $\sin^2\theta_{23}$ being taken to be 0.5. The values of $\sin^2\theta_{23}$ away from 0.5 would make the contours asymmetric and would give rise to some sensitivity to the octant of θ_{23} , as we shall see later.

Figure 6: The precision reach expected at ICAL in the $\sin^2 \theta_{23} - |\Delta m_{32}^2|$ plane at various confidence levels. The black(broken), blue(dotted) and red(solid) lines show 68%, 90% and 99% C.L contours. The true values of $\sin^2 \theta_{23}$ and $|\Delta m_{32}^2|$ used for generating data are shown by the black dots. The true values of other parameters used are given in Table 2. Panel (a) is for five-year running of the 50 kt detector while (b) is for ten years exposure.

Note that in our analysis, we have taken $\cos \theta$ bins of width 0.1. The muon angle resolution in ICAL is however better than 1° for almost all values of the zenith angle. The reason we had to take such wide angle bins is because of limited statistics. In order to study the impact of our choice of binning on the precision measurements of $\sin^2 \theta_{23}$ and $|\Delta m_{32}^2|$ in ICAL, we reduce the $\cos \theta$ bin size to 0.05 and the size of the E bins to 0.5 GeV. In Fig. 7, we show the effect of taking these finer bins in E and $\cos \theta$ on the precision reach of the two parameters. The figure corresponds to 10 years of ICAL exposure. We see that the finer bins bring only a marginal improvement in the precision measurement of both $\sin^2 \theta_{23}$ and $|\Delta m_{32}^2|$. For further results in this paper, we continue to use energy bins of width 1 GeV and zenith angle bins of width 0.1. The optimization with variable bin widths will be a part of future work.

In fig. 8 we show the comparison of the precision reach on the atmospheric neutrino oscillation parameters at ICAL with that obtained from other experiments currently. Note that here we use the parameter $\sin^2 2\theta_{23}$ instead of $\sin^2 \theta_{23}$ in order to enable a direct comparison. The blue and red lines show the expected sensitivity from atmospheric neutrino measurements at ICAL after 5 years and the 10 years exposure, respectively. The green line is the 90% C.L.-allowed contour obtained by the zenith angle analysis of SK atmospheric neutrino measurements (shown at the Neutrino 2012 conference), while the pink line is the contour obtained by their L/E analysis [40]. The black line shows the 90% C.L. allowed region given by the combined analysis of the full MINOS data including 10.71×10^{20} POT for the ν_μ -beam, 3.36×10^{20} POT for the $\bar{\nu}_\mu$ -beam, as well as the atmospheric neutrino data corresponding to an exposure of 37.9 kt-years [41].

Figure 7: Effect of binning on the precision reach expected from the analysis of $50 \text{ kt} \times 10 \text{ years}$ data of atmospheric neutrinos in ICAL. The black, blue and red lines show 68%, 90% and 99% C.L contours. The solid lines show the contours for $(E, \cos \theta)$ bin widths of $(1 \text{ GeV}, 0.1)$ while the broken lines show the contours for $(E, \cos \theta)$ bin widths of $(0.5 \text{ GeV}, 0.05)$.

Figure 8: Comparison of the reach of ICAL@INO with the current results from other neutrino experiments. The black dot in the figure denotes the point where the ICAL data was generated. The true values of the other oscillation parameters are given in Table 2.

From fig. 8 it may be observed that, with 5 years of exposure, ICAL will be able to almost match the precision on $|\Delta m_{32}^2|$ obtained from the SK L/E analysis currently. With 10 years data this will improve, though it will still not be comparable to the precision we already have from the MINOS experiment. Since the direction of neutrinos in MINOS is known accurately, their L/E is known to a greater precision and their measurement of $|\Delta m_{32}^2|$ is consequently more accurate. The precision of ICAL on $\sin^2 2\theta_{23}$ in 10 years may be expected to be comparable to what we currently have from SK. (Of course by the time ICAL completes 10 years, SK would have gathered even more data.) This precision is controlled to a large extent by the total number of events. We can see that the sensitivity of ICAL to $\sin^2 2\theta_{23}$ and $|\Delta m_{32}^2|$ is not expected to surpass the precision we already have from the current set of experiments. In fact, the precision on these parameters are expected to improve significantly with the expected data from T2K [9, 42] and NO ν A [21], and ICAL will not be competing with them as far as these precision measurements are concerned. The ICAL data will however give complementary information on these parameters, which will significantly contribute to the improvement of the precision on the global fit.

Earth matter effects in atmospheric neutrinos can be used to distinguish maximal from non-maximal θ_{23} mixing and can lead to the determination of the correct θ_{23} octant [43–45]. We show in Fig. 9 the potential of 10 years of ICAL run for distinguishing a non-maximal value of θ_{23} from maximal mixing in the case where $\sin^2 2\theta_{23} = 0.90$ ($\sin^2 \theta_{23} = 0.342, 0.658$) and $\sin^2 2\theta_{23} = 0.95$ ($\sin^2 \theta_{23} = 0.388, 0.612$). Note that the current 3σ allowed range of $\sin^2 2\theta_{23}$ is $(0.91, 1.0)$. The figure shows that, if the value of θ_{23} is near the current 3σ bound and in the first octant, then it may be possible to exclude maximal mixing to 99% C.L. with this 2-parameter analysis. If θ_{23} is in the second octant, or if $\sin^2 2\theta_{23}$ is larger than 0.9, the exclusion of the maximal mixing becomes a much harder task.

Fig. 9 can also be used to quantify the reach of ICAL for determining the correct octant of θ_{23} , if the value of $\sin^2 2\theta_{23}$ is known. This can be seen by comparing the χ^2 value corresponding to the true value of $\sin^2 \theta_{23}$, but in the wrong octant, with that corresponding to the true value of $\sin^2 \theta_{23}$. We find that, for $\sin^2 2\theta_{23} = 0.9$, i.e. just at the allowed 3σ bound, the octant can be identified at $>95\%$ C.L. with 10 years of ICAL run if θ_{23} is in the first octant. However if θ_{23} is in the second octant, the identification of the octant would be much harder: θ_{23} in the wrong octant can be disfavored only to about 85% C.L.. The situation is more pessimistic if $\sin^2 2\theta_{23}$ is closer to unity.

The precision on $|\Delta m_{32}^2|$ will keep improving with ongoing and future long baseline experiments. The inclusion of the information may improve the chance of ICAL@INO being able to identify deviation of θ_{23} from maximal mixing and its octant to some extent, however that exercise is beyond the scope of this paper.

Figure 9: The projected reach in the $\sin^2 \theta_{23} - |\Delta m_{32}^2|$ plane for four different non-maximal choices of θ_{23} . The black(broken), blue(dotted) and red(solid) lines show 68%, 90% and 99% C.L. contours for 10 years of 50 kt ICAL run. Note that we use normal hierarchy, and assume that it is already known.

5 Summary

In the analysis, we have calculated the projected reach of the ICAL experiment at INO for precise determination of the atmospheric neutrino parameters. We have used NUANCE simulated data on muon energies and directions using the resolutions and efficiencies obtained from a complete detector simulation by the INO collaboration. We incorporate the oscillation physics using the re-weighting method and calculate the values of χ^2 in the $\sin^2 \theta_{23} - |\Delta m_{32}^2|$ plane using the pull method that takes into account systematic errors on (i) flux normalization (ii) cross sections (iii) neutrino flux tilt (iv) zenith angle dependence of flux and (v) overall systematic error.

We present uncorrelated as well as correlated constraints on the value of $\sin^2 \theta_{23}$ and $|\Delta m_{32}^2|$ expected to be obtained after 10 years of running of the 50 kt ICAL. We find that the values of $\sin^2 \theta_{23}$ and $|\Delta m_{32}^2|$ may be determined at an accuracy of 17% and 5.1% respectively. The sensitivities with the data at ICAL only are not expected to be better than what we already have, indeed some of the other experiments in the next decade may do much better. However the

measurement at ICAL will be complementary and may be expected to contribute significantly towards the precision of parameters in a global fit.

As far as the sensitivity to the θ_{23} octant and its deviation from maximality is concerned, we find that 10 years of ICAL can exclude maximal mixing or the θ_{23} value in the other octant to $>95\%$ C.L. only if the actual θ_{23} is in the first octant and close to the current 3σ lower bound to 99% C.L.. Indeed, the octant identification seem to be beyond the reach of any single experiment in the next decade.

This paper presents the first study on the reach of ICAL@INO for precision of atmospheric neutrino parameters, using the complete detector simulation. Note that in this analysis we have used only the information on muon events. However, the ICAL atmospheric neutrino experiment will also record and measure the hadrons associated with the charged current interaction of the muon-type neutrinos. Inclusion of this data-set into the analysis is expected to provide energy and angle reconstruction of the neutrino. This could lead to an improved sensitivity of the detector to the oscillation parameters. The analysis including the hadrons along with the muons is a part of the ongoing effort of the INO-ICAL collaboration. In addition, the updates and improvements in the muon momentum reconstruction algorithm as well as the optimization of our analysis procedure are likely to improve the results presented in this paper.

6 Acknowledgemets

This work is a part of the ongoing effort of INO-ICAL collaboration to study various physics potential of the proposed INO-ICAL detector. Many members of the collaboration have contributed for the completion of this work. We are very grateful to G. Majumder and A. Redij for their developmental work on the ICAL detector simulation package. We also thank A. Chatterjee, K. Meghna, K. Rawat, D. Indumathi for their contributions in characterizing the muon detector response of the ICAL detector. In addition, we thank N. Mondal, D. Indumathi, S. Uma Sankar, S. Goswami, N. Sinha, P. Ghoshal and M. Naimuddin for intensive discussions on the oscillation analysis in regular meetings. T.T. thanks Costas Andreopoulos for discussions on the neutrino event generators. A.D. and S.C. acknowledge partial support from the European Union FP7 ITN INVISIBLES (Marie Curie Actions,PITN-GA-2011-289442). Finally we thank V. Datar, K. Kar and A. Raychaudhuri for critical reading of the manuscript.
